

React Interview Questions

React is an efficient, declarative, and flexible open-source JavaScript library for building simple, fast and scalable front-ends.

For developers coming from JavaScript background, the process of developing web applications becomes easier.

Let's understand the core concepts of React, by answering the frequently asked interview questions.

1. What are the advantages of using React?
2. What is JSX?
3. What are the differences between functional and class components?
4. What is the virtual DOM? How does react use the virtual DOM to render the UI?
5. What are the differences between controlled and uncontrolled components?
6. What are the different lifecycle methods in React?
7. Explain Strict Mode in React.
8. How to prevent re-renders in React?
9. Explain React state and props.
10. Explain React Hooks.
11. What are the different ways to style a React component?
12. Name a few techniques to optimize React app performance.
13. What are keys in React?
14. How to pass data between react components?
15. What are Higher Order Components?
16. What is prop drilling in React?
17. What are error boundaries?

1. What are the advantages of using React?

X

DOM is a virtual new virtual DOM side the browser.

Anyone with little

easily navigated in EO of an app.

Components are d across various uses the pace of

for developing an

t using functions

createElement()

ss:

Using JSX, the above code can be simplified:

```
const container = (
  <div>
    <p>This is a text</p>
  </div>
);
ReactDOM.render(container,RootElement);
```

As one can see in the code above, we are directly using HTML inside JavaScript.

3. What are the differences between functional and class components?

Before the introduction of Hooks in React, functional components were called stateless components and were behind class components on feature basis. After the introduction of Hooks, functional components are equivalent to class components.

Although functional components are the new trend, the react team insists on keeping class components in React. Therefore, it is important to know how these both components differ. On the following basis let's compare functional and class components:

- Declaration

Functional components are nothing but JavaScript functions and therefore can be declared using an **arrow function** or the **function** keyword:

```
function card(props){
  return(
    <div className="main-container">
      <h2>Title of the card</h2>
    </div>
  )
}

const card = (props) =>{
  return(
    <div className="main-container">
      <h2>Title of the card</h2>
    </div>
  )
}
```

Class components on the other hand, are declared using the ES6 class:

```
class Card extends React.Component{
  constructor(props){
    super(props);
  }

  render(){
    return(
      <div className="main-container">
        <h2>Title of the card</h2>
      </div>
    )
  }
}
```

■ Handling props

Let's render the following component with props and analyse how functional and class components handle props:

```
<StudentInfo name="Vivek" rollNumber="23" />
```

In functional components, the handling of props is pretty straight forward. Any prop provided as an argument to a functional component, can be directly used inside HTML elements:

```
function StudentInfo(props){
  return(
    <div className="main">
      <h2>{props.name}</h2>
      <h4>{props.rollNumber}</h4>
    </div>
  )
}
```

In the case of class components, props are handled in a different way:

```
class StudentInfo extends React.Component{
  constructor(props){
    super(props);
  }

  render(){
    return(
      <div className="main">
        <h2>{this.props.name}</h2>
        <h4>{this.props.rollNumber}</h4>
      </div>
    )
  }
}
```

As we can see in the code above, **this** keyword is used in the case of class components.

- Handling state

Functional components use React hooks to handle state.

It uses the **useState** hook to set state of a variable inside the component:

```
function ClassRoom(props){  
  let [studentsCount, setStudentsCount] = useState(0);  
  
  const addStudent = () => {  
    setStudentsCount(++studentsCount);  
  }  
  return(  
    <div>  
      <p>Number of students in class room: {studentsCount}</p>  
      <button onClick={addStudent}>Add Student</button>  
    </div>  
  )  
}
```

Since useState hook returns an array of two items, the first item contains the current state, and the second item is a function used to update the state.

In the code above, using array destructuring we have set the variable name to studentsCount with a current value of “0” and setStudentsCount is the function that is used to update the state.

For reading the state, we can see from the code above, the variable name can be directly used to read the current state of the variable.

We cannot use React Hooks inside class components, therefore state handling is done very differently in a class component:

Let's take the same above example and convert it into a class component:

```

class ClassRoom extends React.Component{
    constructor(props){
        super(props);
        this.state = {studentsCount: 0};

        this.addStudent = this.addStudent.bind(this);
    }

    addStudent(){
        this.setState((prevState)=>{
            return {studentsCount: prevState.studentsCount++}
        });
    }

    render(){
        return(
            <div>
                <p>Number of students in class room: {this.state.studentsCount}</p>
                <button onClick={this.addStudent}>Add Student</button>
            </div>
        )
    }
}

```

In the code above, we see we are using **this.state** to add the variable **studentsCount** and setting the value to "0".

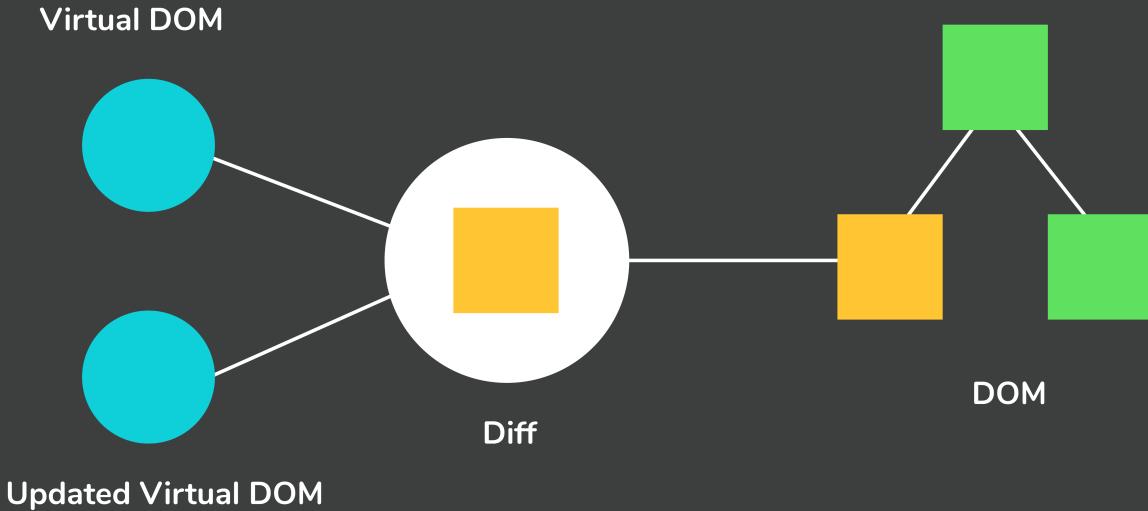

For reading the state, we are using **this.state.studentsCount**.

For updating the state, we need to first bind the **addStudent** function to **this**. Only then, we will be able to use the **setState** function which is used to update the state.

4. What is the virtual DOM? How does react use the virtual DOM to render the UI?

As stated by the react team, virtual DOM is a concept where a virtual representation of the real DOM is kept inside the memory and is synced with the real DOM by a library such as ReactDOM.

Document Object Model

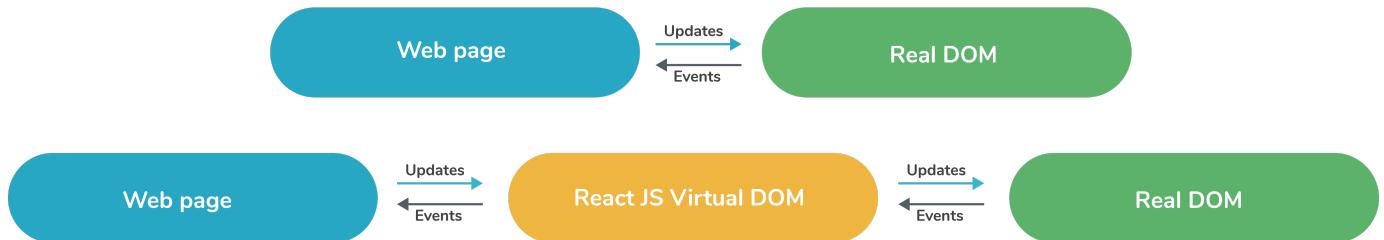

Why was virtual DOM introduced? DOM manipulation is an integral part of any web application, but DOM manipulation is quite slow when compared to other operations in JavaScript. The efficiency of the application gets affected when several DOM manipulations are being done. Most JavaScript frameworks update the entire DOM even when a small part of the DOM changes.

For example, consider a list that is being rendered inside the DOM. If one of the items in the list changes, the entire list gets rendered again instead of just rendering the item that was changed/updated. This is called inefficient updating.

To address the problem of inefficient updating, the react team introduced the concept of virtual DOM.

How does it work?

Real & Virtual DOMs

For every DOM object, there is a corresponding virtual DOM object(copy), which has the same properties.

The main difference between the real DOM object and the virtual DOM object is that any changes in the virtual DOM object will not reflect on the screen directly. Consider a virtual DOM object as a blueprint of the real DOM object.

Whenever a JSX element gets rendered, every virtual DOM object gets updated.

****Note- One may think updating every virtual DOM object might be inefficient, but that's not the case. Updating the virtual DOM is much faster than updating the real DOM since we are just updating the blueprint of the real DOM.**

React uses two virtual DOMs to render the user interface. One of them is used to store the current state of the objects and the other to store the previous state of the objects.

Whenever the virtual DOM gets updated, react compares the two virtual DOMs and gets to know about which virtual DOM objects were updated.

After knowing which objects were updated, react renders only those objects inside the real DOM instead of rendering the complete real DOM.

This way, with the use of virtual DOM, react solves the problem of inefficient updating.

5. What are the differences between controlled and uncontrolled components?

Controlled and uncontrolled components are just different approaches to handling input form elements in react.

Feature	Uncontrolled	Controlled	Name attrs
One-time value retrieval (e.g. on submit)			
Validating on submit			
Field-level Validation			
Conditionally disabling submit button			
Enforcing input format			
several inputs for one piece of data			
dynamic inputs			☒

Controlled component In a controlled component, the value of the input element is controlled by

React.

We store the state of the input element inside the code, and by using event-based callbacks, any changes made to the input element will be reflected in the code as well.

When a user enters data inside the input element of a controlled component, onChange function gets triggered and inside the code we check whether the value entered is valid or invalid. If the value is valid, we change the state and re-render the input element with new value.

Example of a controlled component:

```
function FormValidation(props) {
  let [inputValue, setInputValue] = useState("");
  let updateInput = e => {
    setInputValue(e.target.value);
  };

  return (
    <div>
      <form>
        <input type="text" value={inputValue} onChange={updateInput} />
      </form>
    </div>
  );
}
```

As one can see in the code above, the value of the input element is determined by the state of the **inputValue** variable. Any changes made to the input element is handled by the **updateInput** function.

Uncontrolled component In an uncontrolled component, the value of the input element is handled by the DOM itself.

Input elements inside uncontrolled components work just like normal HTML input form elements.

The state of the input element is handled by the DOM. Whenever the value of the input element is changed, event-based callbacks are not called. Basically, react does not perform any action when there are changes made to the input element.

Whenever user enters data inside the input field, the updated data is shown directly. To access the value of the input element, we can use **ref**.

Example of an uncontrolled component:

```
function FormValidation(props) {
  let inputValue = React.createRef();

  let handleSubmit = e => {
    alert(`Input value: ${inputValue.current.value}`);
    e.preventDefault();
  };

  return (
    <div>
      <form onSubmit={handleSubmit}>
        <input type="text" ref={inputValue} />
        <button type="submit">Submit</button>
      </form>
    </div>
  );
}
```

As one can see in the code above, we are **not** using **onChange** function to govern the changes made to the input element. Instead, we are using **ref** to access the value of the input element.

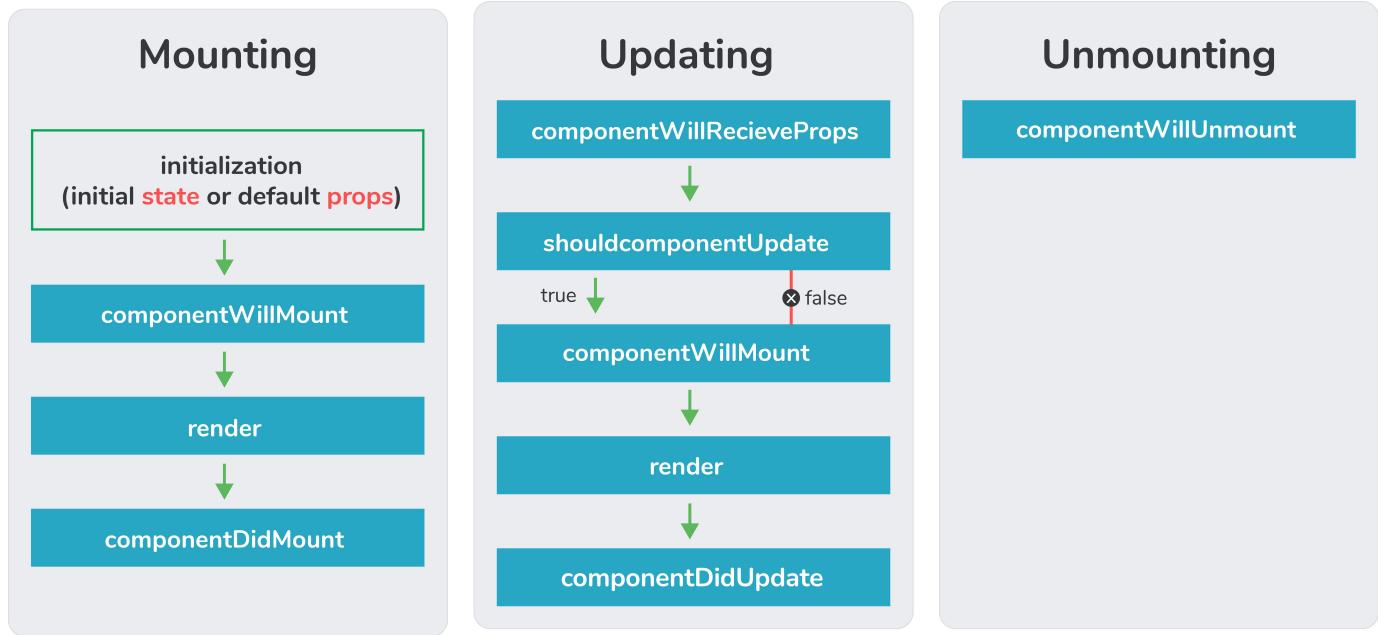

6. What are the different lifecycle methods in React?

Every component in React has lifecycle methods that we can tap into, to trigger changes at a particular phase of the life cycle.

Each component in react goes through three phases: **Mounting, Updating, and Unmounting**.

There are corresponding lifecycle methods for each of the three phases:

****Note- In this article, we are discussing the use of lifecycle methods in class components. For utilising lifecycle methods in functional components, react hooks are used.**

Mounting:

There are four built-in lifecycle methods that are called in the **following order** when a component is mounted:

constructor() - This is called before anything else. We can set the initial state of the component inside this method. The constructor method is used to set the initial state and bind methods to the component.

getDerivedStateFromProps() - This is called before rendering the elements in the DOM.

In this method, we can set the state of the component based on the props we received. This method is used very rarely.

render() - This is the only required method in the class component. This method returns the HTML elements which are going to be rendered inside the DOM.

componentDidMount() - It is called right after the component is rendered inside the DOM. All the statements which require the DOM nodes can be executed in this method. Network requests from a remote end-point can also be instantiated in this method.

Updating:

Updates in react are caused by changes in state or props. Update leads to re-rendering of the component. The following methods are called when a component is re-rendered:

getDerivedStateFromProps() - This method is called again when a component is being re-rendered.

shouldComponentUpdate() - This method is called before rendering the component when new

props are received. It lets React know if the component's output is affected by the newly received props or by the state change. By default, it returns **true**.

render() - To re-render the HTML inside the DOM, the **render()** method gets called again.

getSnapshotBeforeUpdate() - This method is called just before the newly rendered HTML gets committed to the DOM. It stores the previous state of the component so that React has an idea of what parts of the DOM needs to be updated.

componentDidUpdate() - It is called after the component gets re-rendered. This method works just like the **componentDidMount()** method, the difference is that this method does not get called on initial render.

Unmounting:

componentWillUnmount() - This method is called just before the component gets destroyed. Any clean up statements should be executed inside this method.

7. Explain Strict Mode in React.

StrictMode is a tool added in the **version 16.3** of React to highlight potential problems in an application. It performs additional checks on the application.

```
function App() {
  return (
    <React.StrictMode>
      <div classname="App">
        <Header/>
        <div>
          Page Content
        </div>
        <Footer/>
      </div>
    </React.StrictMode>
  );
}
```

To enable StrictMode, **<React.StrictMode>** tags need to be added inside the application:

```
import React from "react";
import ReactDOM from "react-dom";

import App from "./App";

const rootElement = document.getElementById("root");
ReactDOM.render(
  <React.StrictMode>
    <App />
  </React.StrictMode>,
  rootElement
);
```

StrictMode currently helps with the following issues:

- **Identifying components with unsafe lifecycle methods**

Certain lifecycle methods are unsafe to use in asynchronous react applications. With the use of third-party libraries it becomes difficult to ensure that certain lifecycle methods are not used.

StrictMode helps in providing us a warning if any of the class components uses an unsafe lifecycle method.

- **Warning about the usage of legacy string API**

If one is using an older version of React, **callback ref** is the recommended way to manage **refs** instead of using the **string refs**. StrictMode gives a warning if we are using **string refs** to manage refs.

- **Warning about the usage of findDOMNode**

Previously, **findDOMNode()** method was used to search the tree of a DOM node. This method is deprecated in React. Hence, the StrictMode gives us a warning about the usage of this method.

- **Warning about the usage of legacy context API (because the API is error-prone)**

8. How to prevent re-renders in React?

Reason for re-renders in React:

Re-rendering of a component and its child components occur when props or state of the component has been changed.

Re-rendering components that are not updated, affects the performance of an application.

How to prevent re-rendering:

Consider the following components:

```

class Parent extends React.Component {
  state = { messageDisplayed: false };
  componentDidMount() {
    this.setState({ messageDisplayed: true });
  }

  render() {
    console.log("Parent is getting rendered");
    return (
      <div className="App">
        <Message />
      </div>
    );
  }
}

class Message extends React.Component {
  constructor(props) {
    super(props);
    this.state = { message: "Hello, this is vivek" };
  }
  render() {
    console.log("Message is getting rendered");
    return (
      <div>
        <p>{this.state.message}</p>
      </div>
    );
  }
}

```

Parent component is the parent component and **Message** is the child component. Any change in the parent component will lead to re-rendering of the child component as well.

To prevent the re-rendering of child component, we use the `shouldComponentUpdate()` method:

****Note- Use `shouldComponentUpdate()` method only when you are sure that it's a static component.**

```

class Message extends React.Component {
  constructor(props) {
    super(props);
    this.state = { message: "Hello, this is vivek" };
  }
  shouldComponentUpdate() {
    console.log("Does not get rendered");
    return false;
  }
  render() {
    console.log("Message is getting rendered");
    return (
      <div>
        <p>{this.state.message}</p>
      </div>
    );
  }
}

```

As one can see in the code above, we have returned **false** from the `shouldComponentUpdate()` method, which prevents the child component from re-rendering.

9. Explain React state and props.

Props	State
Immutable	Owned by its component
Has better performance	Locally scoped
Can be passed to child components	Writable/Mutable has <code>setState()</code> method to modify properties Changes to state can be asynchronous can only be passed as props

React State

Every component in react has a built-in **state** object, which contains all the property values that belong to that component.

In other words, **the state object** controls the behaviour of a component. Any change in the property values of the state object leads to re-rendering of the component.

****Note- State object is not available in functional components but, we can use React Hooks to add state to a functional component.**

How to declare a state object?

Example:

```
class Car extends React.Component{
  constructor(props){
    super(props);
    this.state = {
      brand: "BMW",
      color: "black"
    }
  }
}
```

How to use and update the state object?

```
class Car extends React.Component {
  constructor(props) {
    super(props);
    this.state = {
      brand: "BMW",
      color: "Black"
    };
  }

  changeColor() {
    this.setState(prevState => {
      return { color: "Red" };
    });
  }

  render() {
    return (
      <div>
        <button onClick={() => this.changeColor()}>Change Color</button>
        <p>{this.state.color}</p>
      </div>
    );
  }
}
```

As one can see in the code above, we can use the state by calling **this.state.propertyName** and we can change the state object property using **setState** method.

React Props

Every react component, accepts a single object argument called **props** (which stands for “properties”).

These props can be passed to a component using HTML attributes and the component accepts these props as an argument.

Using props, we can pass data from one component to another.

Passing props to a component:

While rendering a component, we can pass the props as a HTML attribute:

```
<Car brand="Mercedes"/>
```

The component receives the props:

In Class component:

```
class Car extends React.Component {  
  constructor(props) {  
    super(props);  
    this.state = {  
      brand: this.props.brand,  
      color: "Black"  
    };  
  }  
}
```

In Functional component:

```
function Car(props) {  
  let [brand, setBrand] = useState(props.brand);  
}
```

****Note- Props are read-only. They cannot be manipulated or changed inside a component.

10. Explain React Hooks.

What are Hooks? Hooks are functions that let us “hook into” React state and lifecycle features from a functional component.

React Hooks **cannot** be used in class components. They let us write components without class.

Why were Hooks introduced in React?

React hooks were introduced in the 16.8 version of React.

Previously, functional components were called stateless components. Only class components were used for state management and lifecycle methods.

The need to change a functional component to a class component, whenever state management or lifecycle methods were to be used, led to the development of Hooks.

Example of a hook:

useState hook:

In functional components, useState hook lets us define state for a component:

```
function Person(props) {  
  // We are declaring a state variable called name.  
  // setName is a function to update/change the value of name  
  let [name, setName] = useState("");  
}
```

The state variable “name” can be directly used inside the HTML.

11. What are the different ways to style a React component?

There are many different ways through which one can style a React component. Some of the ways are :

- **Inline Styling**

We can directly style an element using inline style attributes.

Make sure the value of style is a JavaScript object:

```
class RandomComponent extends React.Component {  
  render() {  
    return (  
      <div>  
        <h3 style={{ color: "Yellow" }}>This is a heading</h3>  
        <p style={{ fontSize: "32px" }}>This is a paragraph</p>  
      </div>  
    );  
  }  
}
```

- **Using JavaScript object**

We can create a separate JavaScript object and set the desired style properties.

This object can be used as the value of the inline style attribute.

```

class RandomComponent extends React.Component {
  paragraphStyles = {
    color: "Red",
    fontSize: "32px"
  };

  headingStyles = {
    color: "blue",
    fontSize: "48px"
  };

  render() {
    return (
      <div>
        <h3 style={this.headingStyles}>This is a heading</h3>
        <p style={this.paragraphStyles}>This is a paragraph</p>
      </div>
    );
  }
}

```

■ CSS Stylesheet

We can create a separate CSS file and write all the styles for the component inside that file. This file needs to be imported inside the component file.

```

import './RandomComponent.css';

class RandomComponent extends React.Component {
  render() {
    return (
      <div>
        <h3 className="heading">This is a heading</h3>
        <p className="paragraph">This is a paragraph</p>
      </div>
    );
  }
}

```

■ CSS Modules

We can create a separate CSS module and import this module inside our component. Create a file with “.module.css” extension,

styles.module.css:

```

.paragraph{
  color:"red";
  border:1px solid black;
}

```

We can import this file inside the component and use it:

```
import styles from './styles.module.css';

class RandomComponent extends React.Component {
  render() {
    return (
      <div>
        <h3 className="heading">This is a heading</h3>
        <p className={styles.paragraph} >This is a paragraph</p>
      </div>
    );
  }
}
```

12. Name a few techniques to optimize React app performance.

There are many ways through which one can optimize the performance of a React app, let's have a look at some of them:

- **Using useMemo() -**

It is a React hook that is used for caching CPU-Expensive functions.

Sometimes in a React app, a CPU-Expensive function gets called repeatedly due to re-renders of a component, which can lead to slow rendering.

useMemo() hook can be used to cache such functions. By using useMemo(), the CPU-Expensive function gets called only when it is needed.

- **Using React.PureComponent -**

It is a base component class that checks state and props of a component to know whether the component should be updated.

Instead of using the simple React.Component, we can use React.PureComponent to reduce the re-renders of a component unnecessarily.

- **Maintaining State Colocation -**

This is a process of moving the state as close to where you need it as possible.

Sometimes in React app, we have a lot of unnecessary states inside the parent component which makes the code less readable and harder to maintain. Not to forget, having many states inside a single component leads to unnecessary re-renders for the component.

It is better to shift states which are less valuable to the parent component, to a separate component.

■ Lazy Loading -

It is a technique used to reduce the load time of a React app. Lazy loading helps reduce the risk of web app performances to minimal.

13. What are keys in React?

The “React Way” to render a List

Use Array .map

Not a for loop

Give each item a unique key

Avoid using array index as the key

A key is a special string attribute that needs to be included when using lists of elements.

Example of a list using key:

```
const ids = [1, 2, 3, 4, 5];
const listElements = ids.map((id)=>{
  return(
    <li key={id.toString()}>
      {id}
    </li>
  )
})
```

Importance of keys

Keys help react identify which elements were added, changed or removed.

Keys should be given to array elements for providing a unique identity for each element.

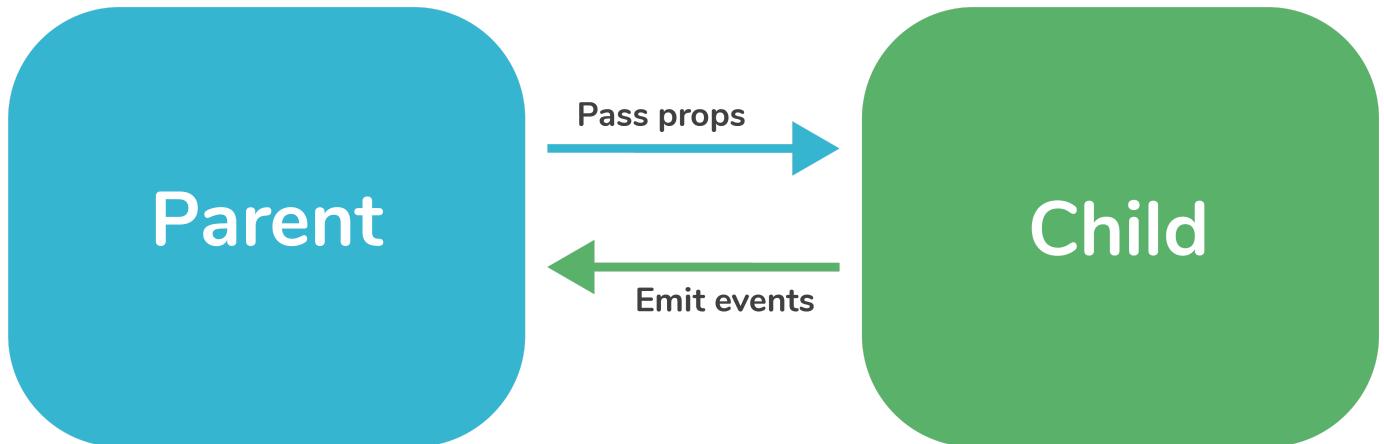

Without keys, React does not understand the order or uniqueness of each element.

With keys, React has an idea of which particular element was deleted, edited, and added.

Keys are generally used for displaying a list of data coming from an API.

*****Note- Keys used within arrays should be unique among siblings. They need not be globally unique.**

14. How to pass data between react components?

Parent Component to Child Component (using props)

With the help of props, we can send data from a parent to a child component.

How do we do this?

Consider the following Parent Component:

```
import ChildComponent from "./Child";

function ParentComponent(props) {
  let [counter, setCounter] = useState(0);

  let increment = () => setCounter(counter + 1);

  return (
    <div>
      <button onClick={increment}>Increment Counter</button>
      <ChildComponent counterValue={counter} />
    </div>
  );
}
```

As one can see in the code above, we are rendering the child component inside the parent component, by providing a prop called counterValue. Value of the counter is being passed from the parent to the child component.

We can use the data passed by the parent component in the following way:

```
function ChildComponent(props) {  
  return (  
    <div>  
      <p>Value of counter: {props.counterValue}</p>  
    </div>  
  );  
}
```

We use the **props.counterValue** to display the data passed on by the parent component.

Child Component to Parent Component (using callbacks)

This one is a bit tricky. We follow the steps below:

- Create a callback in the parent component which takes in the data needed as a parameter.
- Pass this callback as a prop to the child component.
- Send data from the child component using the callback.

We are considering the same example above but in this case, we are going to pass the updated **counterValue** from child to parent.

Step1 and Step2: Create a callback in the parent component, pass this callback as a prop.

```
function ParentComponent(props) {  
  let [counter, setCounter] = useState(0);  
  
  let callback = valueFromChild => setCounter(valueFromChild);  
  
  return (  
    <div>  
      <p>Value of counter: {counter}</p>  
      <ChildComponent callbackFunc={callback} counterValue={counter} />  
    </div>  
  );  
}
```

As one can see in the code above, we created a function called **callback** which takes in the data received from the child component as a parameter.

Next, we passed the function **callback** as a prop to the child component.

Step3: Pass data from child to the parent component.

```

function ChildComponent(props) {
  let childCounterValue = props.counterValue;

  return (
    <div>
      <button onClick={() => props.callbackFunc(++childCounterValue)}>
        Increment Counter
      </button>
    </div>
  );
}

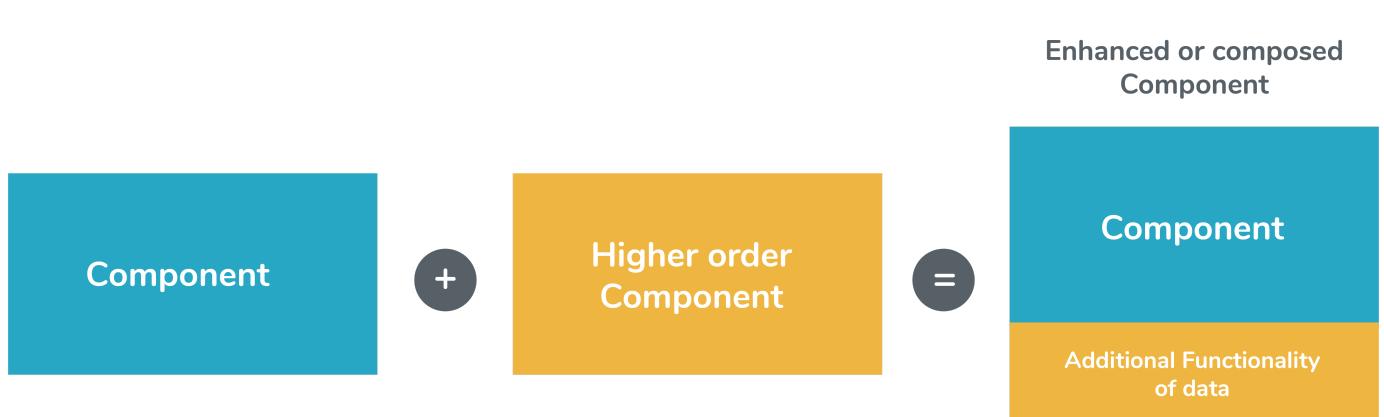

```

In the code above, we have used the **props.counterValue** and set it to a variable called **childCounterValue**.

Next, on button click, we pass the incremented childCounterValue to the **props.callbackFunc**. This way, we can pass data from the child to the parent component.

15. What are Higher Order Components?

Simply put, Higher Order Component(HOC) is a function that takes in a component and returns a new component.

When do we need a Higher Order Component?

While developing React applications, we might develop components that are quite similar to each other with minute differences.

In most cases, developing similar components might not be an issue but, while developing larger applications we need to keep our code **DRY**, therefore, we want an **abstraction** that allows us to define this logic in a single place and share it across components.

HOC allows us to create that abstraction.

Example of a HOC:

Consider the following components having similar functionality

The following component displays the list of articles:

```
// "GlobalDataSource" is some global data source
class ArticlesList extends React.Component {
  constructor(props) {
    super(props);
    this.handleChange = this.handleChange.bind(this);
    this.state = {
      articles: GlobalDataSource.getArticles(),
    };
  }

  componentDidMount() {
    // Listens to the changes added
    GlobalDataSource.addChangeListener(this.handleChange);
  }

  componentWillUnmount() {
    // Listens to the changes removed
    GlobalDataSource.removeChangeListener(this.handleChange);
  }

  handleChange() {
    // States gets Update whenever data source changes
    this.setState({
      articles: GlobalDataSource.getArticles(),
    });
  }

  render() {
    return (
      <div>
        {this.state.articles.map((article) => (
          <ArticleData article={article} key={article.id} />
        ))}
      </div>
    );
  }
}
```

The following component displays the list of users:

```

// "GlobalDataSource" is some global data source
class UsersList extends React.Component {
  constructor(props) {
    super(props);
    this.handleChange = this.handleChange.bind(this);
    this.state = {
      users: GlobalDataSource.getUsers(),
    };
  }

  componentDidMount() {
    // Listens to the changes added
    GlobalDataSource.addChangeListener(this.handleChange);
  }

  componentWillUnmount() {
    // Listens to the changes removed
    GlobalDataSource.removeChangeListener(this.handleChange);
  }

  handleChange() {
    // States gets Update whenever data source changes
    this.setState({
      users: GlobalDataSource.getUsers(),
    });
  }

  render() {
    return (
      <div>
        {this.state.users.map((user) => (
          <UserData user={user} key={user.id} />
        ))}
      </div>
    );
  }
}

```

Notice the above components, both have similar functionality but, they are calling different methods to an API endpoint.

Let's create a Higher Order Component to create an abstraction:

```

// Higher Order Component which takes a component
// as input and returns another component
// "GlobalDataSource" is some global data source
function HOC(WrappedComponent, selectData) {
  return class extends React.Component {
    constructor(props) {
      super(props);
      this.handleChange = this.handleChange.bind(this);
      this.state = {
        data: selectData(GlobalDataSource, props),
      };
    }

    componentDidMount() {
      // Listens to the changes added
      GlobalDataSource.addChangeListener(this.handleChange);
    }

    componentWillUnmount() {
      // Listens to the changes removed
      GlobalDataSource.removeChangeListener(this.handleChange);
    }

    handleChange() {
      this.setState({
        data: selectData(GlobalDataSource, this.props),
      });
    }

    render() {
      // Rendering the wrapped component with the latest data
      return <WrappedComponent data={this.state.data} {...this.props} />;
    }
  };
}

```

We know HOC is a function that takes in a component and returns a component.

In the code above, we have created a function called HOC which returns a component and performs a functionality that can be shared across both **ArticlesList** component and **UsersList Component**.

The second parameter in the HOC function is the function that calls the method on the API endpoint.

We have reduced the duplicated code of the **componentDidUpdate** and **componentDidMount** functions.

Using the concept of Higher Order Components, we can now render the **ArticlesList** and **UsersList** component in the following way:

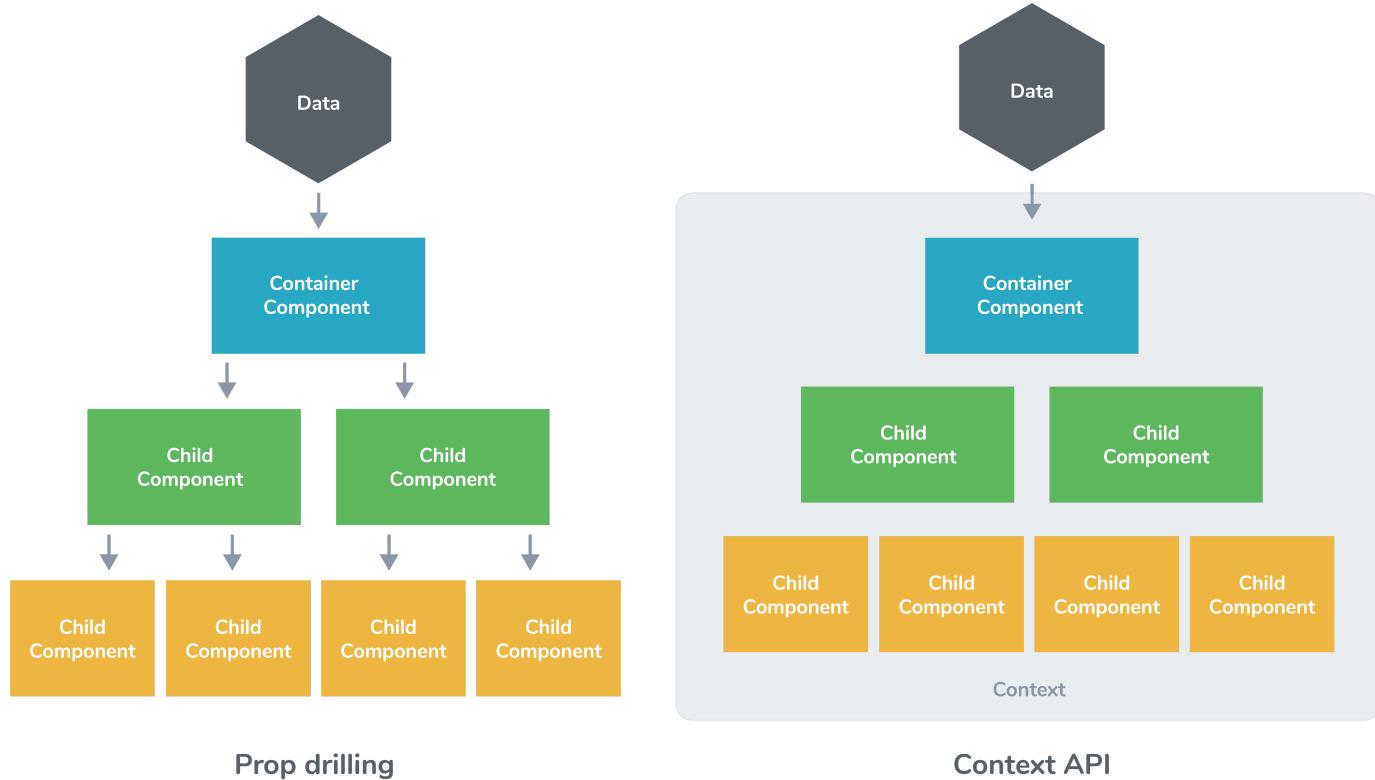

```

const ArticlesListWithHOC = HOC(ArticlesList, (GlobalDataSource) => GlobalD
ataSource.getArticles());
const UsersListWithHOC = HOC(UsersList, (GlobalDataSource) => GlobalDataSou
rce.getUsers());

```

Remember, we are not trying to change the functionality of each component, we are trying to share a single functionality across multiple components using HOC.

16. What is prop drilling in React?

Sometimes while developing React applications, there is a need to pass data from a component that is higher in the hierarchy to a component that is deeply nested.

To pass data between such components, we pass props from a source component, and keep passing the prop to the next component in the hierarchy till we reach the deeply nested component.

The disadvantage of using prop drilling is that the components that should otherwise be not aware of the data have access to the data.

17. What are error boundaries?

Introduced in the version 16 of React, Error boundaries provide a way for us to catch errors that occur in the render phase.

What is an error boundary?

Any component which uses one of the following lifecycle methods, is considered an error boundary.

In what places can an error boundary detect an error?

- Render phase
- Inside a lifecycle method
- Inside the constructor

Without using error boundaries:

```
class CounterComponent extends React.Component{  
  constructor(props){  
    super(props);  
    this.state = {  
      counterValue: 0  
    }  
    this.incrementCounter = this.incrementCounter.bind(this);  
  }  
  
  incrementCounter(){  
    this.setState(prevState => counterValue = prevState+1);  
  }  
  
  render(){  
    if(this.state.counter === 2){  
      throw new Error('Crashed');  
    }  
  
    return(  
      <div>  
        <button onClick={this.incrementCounter}>Increment Value</button>  
        <p>Value of counter: {this.state.counterValue}</p>  
      </div>  
    )  
  }  
}
```

In the code above, when the counterValue equals to 2, we throw an error inside the render method.

When we are not using the error boundary, instead of seeing an error, we see a blank page.

Since any error inside the render method, leads to unmounting of the component.

To display an error that occurs inside the render method, we use error boundaries.

With error boundaries:

As mentioned above, error boundary is a component using one or both of the following methods:

static getDerivedStateFromError and **componentDidCatch**.

Let's create an error boundary to handle errors in render phase:

```
class ErrorBoundary extends React.Component {
  constructor(props) {
    super(props);
    this.state = { hasError: false };
  }

  static getDerivedStateFromError(error) {
    return { hasError: true };
  }
  componentDidCatch(error, errorInfo) {
    logErrorToMyService(error, errorInfo);
  }

  render() {
    if (this.state.hasError) {
      return <h4>Something went wrong</h4>
    }
    return this.props.children;
  }
}
```

In the code above, **getDerivedStateFromError** function renders the fallback UI interface when the render method has an error.

componentDidCatch logs the error information to an error tracking service.

Now with error boundary, we can render the CounterComponent in the following way:

```
<ErrorBoundary>
  <CounterComponent/>
</ErrorBoundary>
```
